Hybrid InSe Nanosheets and MoS$_2$ Quantum Dots for High-Performance Broadband Photodetectors and Photovoltaic Cells

Rajesh Kumar Ulaganathan, Kanchan Yadav, Raman Sankar, Fang Cheng Chou, and Yit-Tsong Chen*

1. Introduction

To find new materials to substitute for conventional silicon (Si)-based technology that has been extensively used in logic circuits for decades, researchers have explored a wide plethora of materials to overcome the scaling limit of Si-based devices. The hybridization of 2D materials and quantum dots (QDs) is one of the ideal platforms for photodetection applications with the merits of high detection sensitivity and wide wavelength coverage. The broadband absorption of a hybrid device stems from various absorbers with multiple bandgaps to create high photocurrent from an efficient exciton generation mechanism under illumination. Here, a new optoelectronic hybrid device of an indium selenide (InSe) nanosheets-based phototransistor is introduced decorated with molybdenum disulfide (MoS$_2$) QDs to possess the photoresponsivity ($R_\lambda$) of 9304 A W$^{-1}$, which is $\approx 10^3$ times higher than $R_\lambda \approx 12.3$ A W$^{-1}$ of the previously reported InSe photodetector. The escalated $R_\lambda$ of this hybrid photodetector is due to the additional injection of photoexcited charge carriers from MoS$_2$ QDs to the InSe phototransistor. Finally, the photovoltaic performance of this MoS$_2$/InSe hybrid device is investigated. The open-circuit voltage ($V_{oc}$) and short-circuit current density ($J_{sc}$) are determined to be 0.52 V and 15.6 mA cm$^{-2}$, respectively, rendering the photovoltaic efficiency of 3.03%. The development of this MoS$_2$/InSe hybrid phototransistor with high device performance and wide wavelength photodetection will bring a new type of optoelectronic applications in the future.
To exploit innovative material characteristics and novel device designs, it is challenging for one material alone to achieve far-reaching applications in modern electronics. Nevertheless, the versatile hybrid devices of p–n, n–n, and p–p junctions have great potential for superior optoelectronic accomplishments.\cite{18–20} Taking advantage of the ease of integration into the complex electronic circuitry, 2D crystals are suitable hybrid materials for developing a new generation of optoelectronics. Recently, hybrid phototransistors have been demonstrated to be of high detection sensitivity and wide wavelength response, which offer a very promising lead in the photodetector technology.\cite{21–24} This burgeoning research gives plenty of exciting explorations of bringing distinctive nanomaterials together for versatile structural engineering and device architectures. In this study, we combined molybdenum disulfide (MoS\textsubscript{2}) quantum dots (QDs) with indium selenide (InSe) nanosheets (denoted simply by MoS\textsubscript{2}/InSe hereafter) to be used as the conducting channel of a hybrid device for high-performance broadband photodetectors and photovoltaic cells.

InSe, belonging to a family of group III–IV layered crystals, is arranged in a honeycomb lattice with four covalently bonded Se-In-In-Se planes, where the adjacent layers are weakly stacked together by van der Waals interaction with an interlayer distance of ∼0.8 nm. InSe is an n-type semiconductor with a direct bandgap of $E_g = 1.3$ eV (for bulk crystal)\cite{25} and possesses excellent photoresponsive characteristics to offer great optoelectronic applications.\cite{26,27} In our earlier study,\cite{28} we demonstrated the photoresponsivity of an InSe field-effect transistor (InSe-FET) to be $12.3$ A W\textsuperscript{-1}. In this report, we prepared a MoS\textsubscript{2}/InSe-FET by incorporating InSe nanosheets with MoS\textsubscript{2} QDs, which were prepared from bulk MoS\textsubscript{2} crystal via a solvothermal method.\cite{29} We enhanced the photoresponsivity of the MoS\textsubscript{2}/InSe-FET to achieve $R_S = 9304$ A W\textsuperscript{-1} at the 488 nm excitation, of which the photoresponsive improvement is $10^3$ times higher than our previous InSe-FET.\cite{28} Like InSe, the MoS\textsubscript{2} layered crystal has attracted great attention because of its tunable optical bandgap,\cite{30} efficient multiple exciton generation,\cite{31} and good stability.\cite{32}

Since the n–n type MoS\textsubscript{2}/InSe heterostructure has a broad absorption profile,\cite{32} we investigated the photoresponsive performance of this hybrid MoS\textsubscript{2}/InSe-FET device from the visible to near-infrared regions. Upon photoexcitation, the junction interfaces and trap states of a MoS\textsubscript{2}/InSe-FET could capture one type of charge carriers to delay the recombination of a free electron–hole pair in the wake of the photon absorption. As a result, other charge carriers with prolonged lifetimes can make several effective transits in the InSe channel between electrodes, leading to high photoconductive gain.\cite{21,23,24} Moreover, the photoinduced electrons in MoS\textsubscript{2} QDs can be transferred to the InSe channel as additional charge carriers,\cite{33} thus enhancing the photoresponsivity to 9304 A W\textsuperscript{-1}. Finally, we also conducted the photovoltaic measurements of this hybrid MoS\textsubscript{2}/InSe-FET device to demonstrate the power conversion efficiency (PCE) of ∼3.03% with short-circuit current density ($J_{sc}$) of 15.6 mA cm\textsuperscript{-2} and open-circuit voltage ($V_{oc}$) of 0.52 V. Consequently, the hybrid MoS\textsubscript{2}/InSe-FET system is found extremely efficient to achieve impressive broadband photodetection and photovoltaic efficiency, which are promising for cost-effective, yet highly responsive, optoelectronic manufactures.

2. Results and Discussion

InSe crystal was grown by the Bridgman technique with the detailed procedures described in the Experimental Section.\cite{16} Figure 1a depicts the crystal structure of InSe with the stacking order via van der Waals interaction between the adjacent InSe layers, which can be exfoliated easily by mechanical exfoliation akin to graphene. In Figure 1b, the X-ray diffraction (XRD) spectrum of the as-synthesized InSe crystal shows the diffraction planes of (002), (004), (006), (008), and (0012) of a hexagonal structure with the lattice constants of $a = 4.005$ Å and $c = 16.64$ Å (Joint Committee on Powder Diffraction Standards (JCPDS)-34-1431). The presence of the In and Se elements in the as-grown InSe crystal was manifested by energy dispersive X-ray (EDX) analysis (Figure S1, Supporting Information).

A field-emission scanning electron microscopy (FE-SEM) image of Figure 1c clearly shows the layered nature of InSe crystal. In Figure 1d, the single crystallinity of the exfoliated InSe crystal is further analyzed by selected-area electron diffraction (SAED), where the hexagonal structure with the Bragg spots of $<1\overline{1}00>$ and $<2\overline{1}1\overline{0}>$ are indicated.\cite{28}

Figure 2a shows the schematic representation of MoS\textsubscript{2} QDs prepared from MoS\textsubscript{2} bulk crystal by a solvothermal method with the detailed synthesis procedures presented in the Experimental Section. After the solvothermal reaction, while cooling the product to room temperature, the sample was settled down for a few hours to separate different sizes of MoS\textsubscript{2} QDs. It is interesting to note that MoS\textsubscript{2} bulk crystal (dark-black color) and MoS\textsubscript{2} QDs (light-yellow color) can be differentiated visually as shown in Figure 2b. The uniform size of MoS\textsubscript{2} QDs, ranging from 3 to 5 nm, was revealed by transmission electron microscopy (TEM) image (Figure 2c), thus demonstrating the successful fragmentation of the MoS\textsubscript{2} bulk structure via the serial sonication and solvothermal reactions. In Figure 2d, the SAED pattern of the as-prepared MoS\textsubscript{2} QDs indicates their polycrystalline structure. Moreover, the elemental compositions of Mo and S in the MoS\textsubscript{2} QDs, revealed by EDX analysis (Figure S2, Supporting Information), confirm the successful sample preparation. We also obtained the Raman spectra of MoS\textsubscript{2} QDs (blue trace) and MoS\textsubscript{2} bulk crystal (black trace) in Figure S3 in the Supporting Information, where the slight blueshift at 378 cm\textsuperscript{-1} ($E_{12g}$) and redshift at 404 cm\textsuperscript{-1} ($A_{1g}$) of MoS\textsubscript{2} QDs (blue line), due to the reduced number of layers from bulk crystal, confirm the presence of MoS\textsubscript{2} QDs.\cite{35}

Figure 3 compares the electrical and optoelectronic properties of the FET devices fabricated by pristine InSe nanosheets alone and the hybrid MoS\textsubscript{2}/InSe heterostructure, respectively. Figure 3a illustrates the schematic diagram of an InSe-FET, where multilayered InSe nanosheets were exfoliated by the Scotch tape method, laid on a silicon wafer of a 300 nm thick SiO\textsubscript{2} oxidized layer, deposited with electrodes (Cr/Au = 5/70 nm in thickness) by evaporation via a shadow-mask technique. In Figure 3b, the thickness of the conducting InSe nanosheets of an InSe-FET (with its optical image shown in the upper inset) was determined to be ∼10 nm by atomic force microscopy (AFM, in the lower inset). Figure 3c illustrates the device architecture of a hybrid MoS\textsubscript{2}/InSe-FET under photoresponsive investigation, where MoS\textsubscript{2} QDs were coated on an InSe-FET by physical adsorption. In the device fabrication, 5 mg mL\textsuperscript{-1} MoS\textsubscript{2} QDs
Figure 1. a) (Top) The 3D view and (bottom) profile view of the InSe crystalline structure with the orange and blue spheres representing the In and Se atoms, respectively. b) The XRD spectrum of the as-synthesized InSe crystal was observed and assigned. c) The layered nature of the InSe crystal is manifested by the observed SEM image. d) The SAED pattern of InSe nanosheets was identified to be a hexagonal single crystal. The inset shows a TEM image of the InSe nanosheets investigated.

Figure 2. a) A schematic representation illustrates the preparation of MoS$_2$ QDs from MoS$_2$ bulk crystal. were diluted in ethanol, spin coated onto the active channel area of an InSe-FET, and annealed at 180 °C for 30 min. The distribution of MoS2 QDs on the channel area of InSe-FET was analyzed by both FE-SEM and EDX mappings, before and after the deposition of MoS2 QDs. After MoS2 QDs were deposited, the random distribution of MoS2 QDs all over the InSe-FET is clearly seen in the SEM image (Figure S4, Supporting Information). Figure 3d shows the output curves (i.e., \( I_{ds} - V_{ds} \) plots) of an InSe-FET and a hybrid MoS2/InSe-FET measured separately in both dark and illuminative states. The inset shows a good contact between the InSe channel and electrodes.

![Figure 3. a) A schematic illustration of an InSe-FET device. b) The thickness of InSe nanosheets, which were used as the conducting channel of an InSe-FET, was determined by AFM. While the top inset represents the optical image of an InSe-FET device, the bottom inset shows the thickness of the conducting channel of InSe nanosheets to be \( \approx 10 \) nm. c) A diagrammatic view of a hybrid MoS2/InSe-FET device under photoresponsive measurements with laser excitation at 488 nm. d) The output curves (i.e., \( I_{ds} - V_{ds} \) plots) of an InSe-FET and a hybrid MoS2/InSe-FET were measured separately in both dark and illuminative states. The inset shows a good contact between the InSe channel and electrodes.](image-url)
which is almost ten times higher than \( R_{\lambda=450\text{nm}} = 12.3 \text{ A W}^{-1} \) \( (P_{\lambda=450\text{nm}} = 0.66 \text{ mW cm}^{-2}) \) of our previously reported pristine InSe-FET.[28] The calculated \( R_{\lambda=488\text{nm}} \) for the MoS\(_2\)/InSe-FET reaches a maximum of 9304 A W\(^{-1} \) at \( P_{\lambda=488\text{nm}} = 0.3 \text{ mW cm}^{-2} \) illumination, which is \( \approx 100 \) times higher than the pristine InSe-FET \( (R_{\lambda=488\text{nm}} = 116 \text{ A W}^{-1}) \) without adding MoS\(_2\) QDs in this study and several times better than other InSe-based 2D heterostructures (as listed in Table S1, Supporting Information).[27,40–42] The escalated \( R_{\lambda=488\text{nm}} \) of the MoS\(_2\)/InSe-FET is due to the injection of additional photoexcited charge carriers from MoS\(_2\) QDs to the InSe channel to enhance the photocurrent. Displayed in Figure 4b is the broadband photoresponse of our hybrid device by measuring the wavelength-dependent \( R_{\lambda} \) at the measuring conditions of \( P_{\lambda} = 0.3 \text{ mW cm}^{-2} \), \( V_{ds} = 10 \text{ V} \), and \( V_{g} = 0 \text{ V} \). The bandgap of InSe nanosheets is \( \approx 1.4 \text{ eV} \)[25]; therefore, the spectral responsivity of the InSe-FET photodetector is active from the near-infrared to visible region (\( R_{\lambda} \approx 22–96 \text{ A W}^{-1} \)). Apparently, the hybrid MoS\(_2\)/InSe-FET has enhanced \( (R_{\lambda} = 25–428 \text{ A W}^{-1}) \) in the same spectral region, because of the presence of MoS\(_2\) QDs (with a bandgap of \( \approx 2.3 \text{ eV} \)) to increase the visible-light absorption. The spectrum of MoS\(_2\) QDs exhibits a strong absorption profile in the visible region (Figure S7, Supporting Information), where the generation of photoexcited carriers could be enhanced and the corresponding photoresponsivity in a MoS\(_2\)/InSe-FET could be escalated via the transfer of the photoexcited carriers to the InSe channel. In comparison, much less improvement was made in the photoresponsivity of the MoS\(_2\)/InSe-FET with the light wavelength longer than \( \approx 800 \text{ nm} \), because of the weak absorption of MoS\(_2\) QDs. This absorption profile of MoS\(_2\) QDs reflects very closely the trend of photoresponsivity of the MoS\(_2\)/InSe-FET (Figure 4b). Table S1 in the Supporting Information compares the \( R_{\lambda} \) of a MoS\(_2\)/InSe-FET with those of the reported photodetectors fabricated with InSe heterostructures.

Next, we turn to the optoelectronic figures of merit, EQE, and specific detectivity (\( D^* \)), for the MoS\(_2\)/InSe-FET photodetector measured at 488 nm as shown in Figure 4c,d, respectively. EQE, defined as the number of electrons detected per incident photon (i.e., the net photon-to-electron conversion), is expressed as \( \text{EQE} = R_{\lambda} \frac{hc}{(e\lambda)} \)[6,39] where \( R_{\lambda} \) is the photoresponsivity, \( h \) is Planck’s constant, \( c \) is the speed of light, \( e \) is the elementary charge, and \( \lambda \) is the wavelength of the incident light. Figure 4c shows the EQEs of \( \approx 10^4 \) and \( \approx 10^6 \) for an InSe-FET and a MoS\(_2\)/InSe-FET, respectively, as a function of incident power at \( \lambda = 488 \text{ nm} \). Notably, the EQE of the MoS\(_2\)/InSe-FET is greater than those of the other reported hybrid photodetectors.[27,40–42] The high EQE can be accounted for by the high \( R_{\lambda} \) and large surface-to-volume ratios of the hybrid MoS\(_2\)/InSe heterostructure, of which both factors facilitate the photoabsorption of MoS\(_2\)/InSe significantly. Upon light illumination, electron–hole pairs were created by photoexcitation, giving rise to the photoinduced current in photodetectors. Before the electron–hole recombination, the photoinduced...
charge carriers could be trapped at the trap/defect states present at the interface of MoS2/InSe or between the InSe channel and silicon-wafer substrate. These captured charge carriers could prolong their lifetime, while the escaping charge carriers moved around the circuit for several times, thus enhancing EQE. Figure S8 in the Supporting Information presents the wavelength-dependent EQEs of an InSe-FET and a MoS2/InSe-FET measured at \( P_\text{sc} = 0.3 \text{ mW cm}^{-2}, \ V_\text{oc} = 10 \text{ V}, \) and \( V_\text{g} = 0 \text{ V}. \)

The \( D^* \) is an indicator of the sensitivity of a photosensor and can be calculated by the relation of \( D^* = R_s S^{1/2} (2eI_{\text{dark}})^{1/2} \), where \( R_s, S, \epsilon, \) and \( I_{\text{dark}} \) are the photoresponsivity, effective area, elemental charge, and dark current, respectively. Photosensitivity is a necessary metric, by which a photodetector can be quantified and compared with other photodetectors irrespective of the device’s dimensions. The above relation can also be derived from \( D^* = (S \Delta f)^{1/2} / \text{NEP} \), where \( S \) is effective area, \( \Delta f \) is the electrical bandwidth of a photodetector, and NEP represents the noise equivalent power, which is the measure of the weakest optical signal that a photodetector can detect. Shown in Figure 4d are the calculated \( D^* \geq 10^{11} \) Jones for an InSe-FET and \( D^* > 10^{13} \) Jones for a hybrid MoS2/InSe-FET (both measured at \( V_\text{ds} = 10 \text{ V} \) and \( V_\text{g} = 0 \text{ V} \)), representing the better detectivities than the commercial Si and some other 2D materials-based photodetectors (e.g., MoS2, InSe, p-GaSe/n-InSe, and Bi2Se3/Si) of \( 10^{11} \)–\( 10^{13} \) Jones. The high \( D^* \) of the MoS2/InSe-FET is attributed to the low \( I_{\text{dark}} \) of pristine (38 nA) and a hybrid MoS2/InSe-FET (50.1 nA) along with high \( R_s \) of this hybrid device. Time-resolved measurements were conducted for the hybrid MoS2/InSe-FET at \( V_\text{ds} = 1 \text{ V} \) and \( V_\text{g} = 0 \text{ V} \) (Figure S9, Supporting Information). In comparison with the rising time \( \approx 50 \text{ ms} \) and relaxation time \( \approx 60 \text{ ms} + 4 \text{ s} \) of an InSe-FET, the photogenerated signal of a hybrid MoS2/InSe-FET has slightly slower responses of \( \approx 120 \text{ ms} \) in rising and \( \approx 120 \text{ ms} + 5 \text{ s} \) in relaxation. The slightly slower responses of a hybrid MoS2/InSe-FET could be due to the presence of a few more trap states and/or the slower charge transfer in the MoS2/InSe interface.

Next, we investigated the photovoltaic performance for the hybrid MoS2/InSe-based device. Figure 5a illustrates schematically the fabricated device architecture of glass/indium tin oxide (ITO)/titanium dioxide (TiO2)/InSe/MoS2/Spiro ometad/Au with their corresponding energy-band alignment given in Figure 5b. It is noted that the InSe/MoS2 heterostructure acted as an active material and the TiO2 and Spiro ometad performed as the electrons and holes transport layers, respectively. While the TiO2 layer was used to collect the electrons arising from the photoexcited InSe/MoS2 heterostructure, the holes transferred to Spiro ometad and were guided to the external circuit. Figure 5c displays the photocurrent density versus voltage (\( J-V \)) curve of the hybrid MoS2/InSe device under AM 1.5 illumination. The \( J-V \) curve of the hybrid MoS2/InSe-based solar cell shows a typical diode behavior. The open-circuit voltage (\( V_\text{oc} \)) and short-circuit current density (\( J_\text{sc} \)) were determined to be 0.52 V and 15.6 mA cm\(^{-2}\), respectively, yielding a photovoltaic PCE of 3.03% for the hybrid solar cell. The fill factor of 0.37 is excellent in comparison with the recently reported InSe-based 2D heterostructure (as listed in Table S2, Supporting Information).

3. Conclusion

In summary, we demonstrated a new hybrid optoelectronic device composed of InSe nanosheets and MoS2 QDs. The device exhibits high \( R_{\text{sc}=48\text{hnm}} = 9304 \text{ A W}^{-1} \) with EQE = 10\(^6\) and \( D^* = 10^{13} \) Jones. The hybrid MoS2/InSe-FET photodetector exhibits a broadband spectral response ranging from the near-infrared (1000 nm) to visible (400 nm) region. We further showed the feasibility of using this hybrid MoS2/InSe device toward the photovoltaic performance and determined its photovoltaic parameters of \( V_\text{oc} = 0.52 \text{ V}, J_\text{sc} = 15.6 \text{ mA cm}^{-2}, \) PCE = 3.03%, and the fill factor of 0.37. In view of the excellent photodetection and photovoltaic characteristics with broadband
photoresponse, this hybrid MoS$_2$/InSe heterostructure holds great potential for high-performance optoelectronic devices in the future applications.

4. Experimental Section

**Crystal Growth—InSe Crystal:** The InSe single crystal was grown with the Bridgman method using the In and Se powders of 99.999% in purity (purchased from Sigma-Aldrich) as reaction precursors. The growth of InSe crystal was performed in quartz ampoules at the pressure of $\approx 7 \times 10^{-2}$ Torr. The ampoules containing the In and Se powders were heated at 850 °C for 24 h; then the ampoules were lowered through a temperature gradient of 1 °C at the rate of 0.1 mm h$^{-1}$. The composition ratios of the as-grown InSe single crystal were characterized to be In (51.9%) and Se (48.1%).[34]

**Crystal Growth—MoS$_2$ Crystal:** The MoS$_2$ single crystal was grown by chemical-vapor-transport (CVT) reaction in a three-zone horizontal furnace. The CVT system comprises a furnace with a quartz tube, closed at one end, of 100 cm in length and 12 cm/10 cm in outer/inner diameter. For the crystal growth, high-quality quartz ampoules of 32 cm in length and 2 cm/1.8 cm in outer/inner diameter were filled with $\approx 20$ g samples containing the stoichiometric proportion (1:1) of Mo (99.999% in purity) and S (99.999% in purity) and were sealed at $10^{-3}$ Torr. By placing the ampoules in the three-zone horizontal furnace, the reaction and growth zones were heated slowly and later maintained at specific temperatures during the growth period.[34]

**MoS$_2$ Quantum Dots:** MoS$_2$ QDs were prepared from MoS$_2$ bulk crystal via the two successive steps of a solvothermal method. In the first step, we obtained MoS$_2$ nanosheets from bulk crystal by sonication. In the second step, MoS$_2$ QDs were obtained from the resultant MoS$_2$ nanosheets with a solvothermal treatment, where liquid exfoliation was performed by continuously sonicating (at 250 W) a mixture of 100 mg MoS$_2$ crystal and 100 mL N-methyl-2-pyrrolidone (NMP) in a serum bottle for 24 h. After the liquid exfoliation, the solution was kept at room temperature for a few hours, decanted the top 2/3 of the solution into another round bottom flask, and followed by stirring and refluxing at 140 °C continuously for 12 h. Finally, the resultant mixtures were kept at room temperature for several hours and then centrifuged at 2000 rpm for 5 min to separate the supernatant from the pellets. The light yellow supernatant of MoS$_2$ QDs was collected for further characterizations.

**Device Fabrication:** Few-layered InSe-FETs were fabricated using a homemade micromanipulator. The source–drain electrodes of Cr/Au (5/70 nm in thickness) on the Si wafer was examined using an optical microscope (Leica, DFC495). The thickness of InSe nanosheets was determined by AFM (Veeco, BioScope SZ).

**Device Characterization:** Crystallographic phases of the as-grown crystals were examined by an X-ray diffractometer (X’Pert PRO-PANalytical, CuK$_\alpha$ radiation). The morphology and elemental compositions were investigated by SEM (FEI, Nova 200). TEM (JEOL, JEM-2100F) was utilized to obtain the crystalline structures and selected-area diffraction (SAED) patterns. The electrical and optical measurements at room temperature were carried out in a probe station (Lakeshore, TTPX) at $10^{-2}$ Torr. The probe station is equipped with a source meter (Keithley, 2636A) and an optical system comprising a He-Ne laser (jDS Uniphase, Novette 1507), a power meter (Ophir, Nova II), a xenon lamp (Newport, 66921), and a monochromator (Acton, SpectraPro-500).
